Summary

Our conventional view of multicellular organisms often overlooks the fact that they are metaorganisms. They consist of a host, which is comprised of both a community of self-replicating cells that can compete as well as cooperate and a community of associated microorganisms. This newly discovered complexity raises a profound challenge: How to maintain such a multicellular association that includes independently replicating units and even different genotypes? Here, we identify competing forces acting at the host tissue level, the host-microbe interface, and within the microbial community as key factors to maintain the metaorganism *Hydra*. Maintenance of host tissue integrity, as well as proper regulation and management of the multiorganismic interactions are fundamental to organismal survival and health. Findings derived from the *in vivo* context of the *Hydra* model may provide one of the simplest possible systems to address questions on how a metaorganism is established and remains in balance over time.

1 | INTRODUCTION

The “metaorganism” concept^{1–4} considers the dynamic communities of microorganisms on epithelial surfaces as an integral part of the functionality of the respective organism itself. Today there is also an increasing appreciation that microbes are an essential part of the animal phenotype influencing fitness and thus ecologically important traits of their hosts.^{5–7} Disease onset is seen as a complex set of interactions among a variety of associated partners that affect the fitness of the collective metaorganism.⁸ Discovering that individuals are not solitary, homogenous entities but consist of complex communities of many species that likely evolved during billion years of coexistence led to the hologenome theory of evolution,^{1,9,10} which considers the holobiont with its hologenome as the unit of selection in evolution (Box 1).

Current research is focused on understanding the general principles by which these complex host-microbe communities function and evolve. Which selective forces drive the evolution of these interactions, ie, how do the associated organisms influence each other's

fitness? Which forces shape the colonizing microbial composition? The recognition that microbes are an integral part of higher organisms, and that they live in a complex and stable community with dynamic interactions both internally and toward the host, often results in the misunderstanding of considering these interactions as purely beneficial and cooperative. In reality, interactions within a given holobiont can range from cooperative to competitive to even parasitic. While in cooperative interactions both partners benefit from each other, competition usually results in resource partitioning.

Due to progress in deep sequencing in the last decade, we got accustomed to the idea of organisms as holobionts and the complexity of interactions between host and associated microbial cells (metaorganisms). However, we often forget that in addition to interactions between host cells and microbes, multicellular organisms per se are a complex “society of cells”^{11,12} consisting of independently replicating cells which adapt their replication rate to the environmental condition. These considerations indicate that ensuring functional homogeneity of tissue and maintaining a multicellular collective should be considered as multilevel phenomena that extend from the cell to the tissue to the organismal—and ultimately to the metaorganismal levels. The considerations also raise a profound and largely unexplored challenge: what

This article is part of a series of reviews covering Microbiome-Immune System Interplay appearing in Volume 279 of *Immunological Reviews*. Peter Deines and Tim Lachnit contributed equally to this work.

Box 1 Terminology metaorganism

Holobiont: Is an eukaryotic host with all its associated microbial partners. This multispecies assemblage includes viruses, phages, eubacteria, archaea, fungi, and protozoa.

Hologenome: Genetic information encoded in the eukaryotic host and all of its associated partners. This collective genome forms the theoretical genetic repertoire of a holobiont.

Metaorganism: Includes the function of a holobiont in a given environment. The function of a holobiont depends on (i) presence and composition of the associated partners, framing the genetic potential of the holobiont the hologenome; (ii) the activity, abundance, and the transcriptional active part of the genome of every single partner of the holobiont; (iii) this subsequently results in interactions between host-microbe and microbe-microbe, which finally must be retained at homeostasis in order to maintain a stable holobiont. To emphasize this highly dynamic functional state (capacity) of a holobiont, we refer to it in the following as metaorganism.

are the mechanisms allowing an organism to function as a multicellular association of independently replicating cells of different genotypes? From an evolutionary biology perspective, multicellular organisms are the result of a “major evolutionary transition” in individuality, where previously independently replicating cells gave up their right on autonomous replication to reproduce only as part of the higher-level entity.^{11,13–15} Resolution of conflict between the cells appears key to such a transition.

Here, we introduce *Hydra* as a valuable model for exploring the competing forces in a metaorganism. *Hydra* is member of the animal phylum cnidaria which are not only among the earliest known phyletic lineages that contain stem cells as well as neurons but also possess most of the gene families found in bilaterians.^{16–20} Similar to other animals, cnidaria are multicellular complex holobionts consisting of the diploblastic animal host and its associated endogenous microbiota. In *Hydra*, host tissue integrity and multicellular organization are defended by both an elaborate innate immune response²¹ and phagocytic processes^{22,23} which together form a robust and critical system through which self is distinguished from non-self, pathogenic signals are recognized and eliminated, and host tissue homeostasis is maintained. In addition, interspecies interactions between the host and its stable microbiome, interactions between photosynthetic algae and their host cells, as well as interactions within the microbial community²⁴ are further important components of the *Hydra* metaorganism. Disturbance or shifts in any of these interactions partners can compromise the health of the whole animal.²⁵ As the uncovered basic molecular machinery can be transliterated to more complex organisms and promises to provide conceptual insights into the complexity of host-microbe interactions, an in-depth knowledge of the basic biology of each of the members of the *Hydra* holobiont and the corresponding interactions might be informative to understanding more complex metaorganisms such as vertebrates and humans. This comparison seems to be important in light of the increasing number of chronic and non-communicable

diseases observed in the last decades and the need for testing the hypothesis that microbial and other environmental challenges are the main causative factors of disease manifestation in genetically susceptible individuals.

2 | CELL-CELL COMPETITION IN THE ANIMAL HOST

Hydra is a unique model system to study tissue homeostasis due to its extraordinary regenerative capacity and the continuous self-renewal and differentiating potential of its epithelial and interstitial stem cells. These properties are related to the fact that these animals continuously reproduce asexually by budding.^{26–28} Regeneration and continuous self-renewal is due to the presence of three stem cell lineages: ectodermal and endodermal epithelial cells and interstitial stem cells.²⁹ The long-term persistence of three independent stem cell lineages in a given organism represents a profound challenge to the animal: how to maintain a cellular collective comprised of reproductively independent cells in a constantly changing environment? From the molecular view, autophagy and apoptosis are generally seen as key mechanisms that maintain the whole organism at the expense of individual cells.^{30–32} Autophagy is a cell protective process with a role in nutrient starvation.³³ When nutrients are restricted, cells elaborate double-walled membranes known as phagophores, which enclose cell constituents to form autophagosomes that subsequently fuse with lysosomes to produce autophagolysosomes. Studies of nutrient deprivation in *Hydra* have shown that well-fed animals starved for 10 days start to induce autophagy.³⁴ In addition, epithelial cells in *Hydra* also possess an intrinsic defense mechanism against competing neighbors which is strictly environment dependent and was described previously²² as apoptosis. *Hydra* polyps grow continuously due to proliferation of epithelial and interstitial stem cells throughout the body column. However, polyps do not increase in size as cells are continuously transferred to asexual buds, which form on the lower body column, and are lost at the tentacle tips and in the basal disk. Budding is dependent on feeding: well-fed polyps produce roughly one bud per day; starved polyps cease to form buds after 1–2 days. Unexpectedly, our early work has shown that this striking dependence of budding on feeding is not due to a change in cell proliferation, as initially anticipated, but rather to apoptosis.²² Rapid cell proliferation detected as an increase in the 3H-thymidine labeling index occurs in both well-fed and starved animals. The increase in cell numbers, however, is dramatically different: cell numbers increase exponentially in fed animals but do not change in starved animals. This difference is due to an increased rate of apoptosis in starving polyps. Bosch and David²² observed a sevenfold increase in epithelial cells containing phagocytized apoptotic bodies in starving polyps compared to well-fed polyps. While these observations clearly indicate that environment-dependent elimination of cells from the epithelium—which we consider to be some form of cell competition—regulates growth in *Hydra*, the important question remains as to which molecular regulators are involved in inter- and intracellular clearance? Studies have consistently revealed that FoxO (Forkhead

box O) transcription factors play an important role in stem cell biology and tissue homeostasis. During aging, for example, the balance of removal and regeneration of cells in tissues becomes disturbed mainly due to a decrease in the regenerative potential of adult stem cells. Conditional deletion of FoxO1/3a/4 in the adult hematopoietic stem cell system of mice leads to apoptosis of hematopoietic stem cells preventing the repopulation of these stem cell populations. Similarly, aged mice in which FoxO3a was deleted display reduced regeneration potential [(35), reviewed in (36)].

To uncover the molecules controlling the continuous self-renewal and differentiation in *Hydra* we used a transcriptomic approach to identify the molecular signatures of *Hydra*'s three stem cell lineages. We showed that FoxO is highly expressed in all three stem cell lineages.^{37,38} Overexpression of FoxO in the multipotent interstitial stem cell lineage increased stem and progenitor cell proliferation and activated expression of stem cell genes such as *nanos* in terminally differentiated somatic cells such as nematocytes.³⁷ Conversely, silencing FoxO in epithelia cells increased the number of terminally differentiated cells and slowed down growth rate.³⁷ Previous work has discovered significant parallels in the regulation of FoxO between *Hydra* and bilaterian animals.^{39,40} Together with our functional studies in transgenic *Hydra*, these results suggest a key role for FoxO in *Hydra*'s remarkable ability to continuously maintain tissue homeostasis. The environment-dependent control of tissue homeostasis raises the question, whether FoxO activity is directly involved in the interaction with the environment.

3 | COMPETING FORCES BETWEEN THE HYDRA EPITHELIUM AND THE COLONIZING MICROBES: KEY ROLES OF AMPs

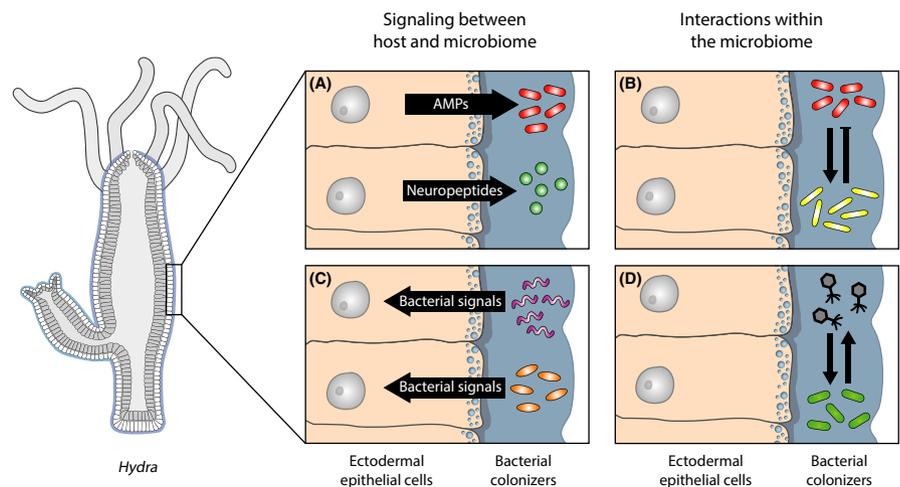

For decades a number of *Hydra* species have been cultivated under standard conditions at constant temperature and identical food. It came as a complete surprise, therefore, that examining the microbiota in different *Hydra* species kept in the laboratory for more than 20 years under controlled conditions revealed an epithelium

colonized by a complex community of microbes, and that individuals from different species differed greatly in their microbiota. Even more astonishing was the finding that individuals living in the wild were colonized by a group of microbes that is similar to that in polyps grown in the laboratory, pointing to the maintenance of specific microbial communities over long periods of time. Bacteria in *Hydra* are specific for any given species.^{41,42} Closely related *Hydra* species as *Hydra vulgaris* and *Hydra magnipapillata* are associated with a very similar microbial community. In contrast, *Hydra oligactis*, the most basal *Hydra* species analyzed so far,⁴³ is associated with the most distinct microbial community compared to the other *Hydra* species. In line with this, comparing the phylogenetic tree of the *Hydra* species with the according cluster tree of associated bacterial communities reveals a high degree of congruency.⁴² This strongly indicates that distinct competing forces are imposed on and within the *Hydra* epithelium.

In the absence of an adaptive immune system, *Hydra* employs an elaborate innate immune system to detect and interact with microbes using their two cell layers as efficient defense barriers.⁴⁴ Invading microorganisms first have to overcome the physicochemical barrier represented by the multilayered glycocalyx that covers the ectodermal epithelium.⁴⁵ Complex cellular and humoral pathways represent the second arm of *Hydra*'s immunity.²¹ Cellular mechanisms include phagocytosis, tissue repair and regeneration, and apoptotic reactions. Apart from these cellular mechanisms, *Hydra* possesses a broad range of antimicrobial factors such as antimicrobial peptides (AMPs; Figure 1) and kazal 2-type protease inhibitors.⁴⁴

Antimicrobial peptides produced in adult polyps include hydra-macin²¹ and arminin⁴⁶ to control bacterial colonization via MyD88 [(47); Figure 2]. Our previous work has shown that AMPs have in addition to their killing activity against pathogens clear regulatory functions in host-microbe homeostasis and are considered as the driving force that leads to changes in microbiota composition. To investigate whether the ectopic expression of an AMP may affect the number and composition of the colonizing microbiota at the ectodermal epithelial surface, we generated transgenic *Hydra* expressing periculin1a in ectoderm epithelial cells.⁴⁸ Comparing the bacterial load of these

FIGURE 1 Modes of signaling and interactions in *Hydra*. (A) Antimicrobial peptides and neuropeptides produced by the host modulate the host-associated microbial community. (B) Microbe-microbe interactions can have a positive, negative, or no impact on the species involved. These ecological interactions are key components of a stable microbiome. (C) Microbially produced metabolites act as signaling molecules on distant targets such as the nerve net. (D) The viral community may contribute to maintaining microbial population equilibrium and community resilience

transgenic polyps with that of wildtype control polyps revealed not only a significantly lower bacterial load in transgenic polyps overexpressing periculin1a but also, unexpectedly, drastic changes in the bacterial community structure. Analyzing the identity of the colonizing bacteria showed that the dominant β -Proteobacteria decreased in number, whereas α -Proteobacteria were more prevalent. Thus, overexpression of periculin causes not only a decrease in the number of associated bacteria but also a changed bacterial composition. With the transgenic polyps overexpressing periculin we apparently have created a new holobiont that is different from all investigated *Hydra* species. From these results we assume that specific associations between hosts and bacteria are a result of bacterial adaptation to different repertoires on AMPs in different host species. Evolutionary changes in the AMP repertoire of host species, therefore, are expected to lead to changes in the composition of the associated bacterial community. These findings support the view that epithelial-derived AMPs are an important regulatory force shaping the composition of epithelial microbiota (Figure 2).

Interestingly, and of significance in the context of environment-dependent control of tissue homeostasis, AMPs were recently discovered to be direct target genes of transcription factor FoxO. Besides its well-known conserved function as major tissue regulator, FoxO modulates the innate immune system in various model organisms including *Drosophila*,^{49,50} *C. elegans*,⁵¹ and *Hydra*.³⁷ In *Hydra*, the microbiome is selectively assembled by a species-specific combination of AMPs which are predominantly expressed in epithelial cells.⁴² Remarkably, loss of tissue homeostasis as well as AMP deficiency result in a decreased potential to select for microbial communities resembling the polyps native microbiota.^{25,42} Transgenic *Hydra* polyps in which the

single FoxO gene is downregulated show in addition to problems in stem cell maintenance a severe change in the immune status and drastically altered expression of AMPs.³⁷ AMPs are also in *Drosophila* well-known effector molecules of the innate immune system and important regulators of the bacterial colonizers. Here, oral microbial infection induces FoxO activity in the intestine, while impaired FoxO signaling decreases resistance to intestinal infections. The inability to raise the expression level of AMPs leads to an elevated bacterial load and a decline in survival.⁵² Thus, transcription factor FoxO appears to combine two functions crucially involved in tissue homeostasis and health in metazoans: FoxO is responsible for stem cell regulation, including tissue maintenance and renewal, and controls the innate immune system. In response to environmental (or bacterial) signals FoxO shuttles between an transcriptionally inactive state in the cytoplasm and an active form in the nucleus thereby serving as an intracellular control board for environmental signals.

The intimacy of the interaction between host and microbiota, as well as the high evolutionary pressure to maintain a specific microbiota, points to the significance of the interkingdom association and implies that hosts deprived of their microbiota should be at a disadvantage. To investigate the effect of absence of microbiota in *Hydra* we have produced gnotobiotic *Hydra* polyps that are devoid of any bacteria. While morphologically no differences could be observed to control polyps, we presented evidence that *Hydra* lacking bacteria suffer from fungal infections unknown in normally cultured polyps.⁵³ Removing the epithelial microbiota results in lethal infection by the filamentous fungus *Fusarium* sp. Restoring the complex microbiota in gnotobiotic polyps prevents pathogen infection. While mono-associations with distinct members of the microbiota fail to provide full protection,

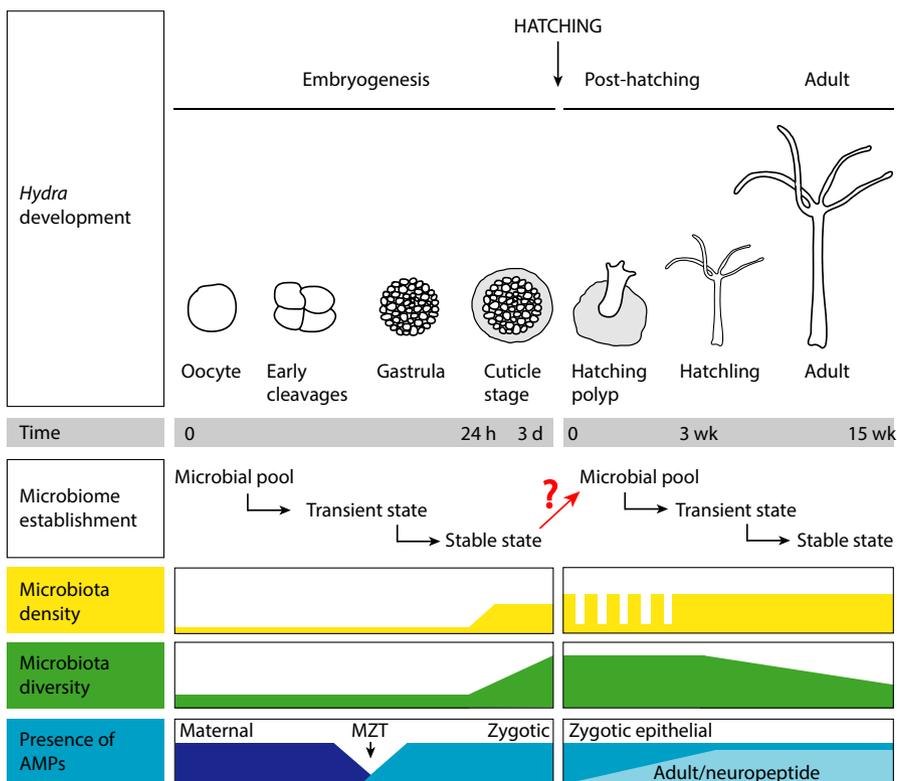

FIGURE 2 Bacterial colonization of *Hydra* during embryogenesis and microbiome progression from posthatching to the adult polyp. Prehatching and posthatching developmental stages are characterized by the expression of specific antimicrobial peptides (AMPs) mediating host-microbe homeostasis. The maternal-zygotic transition (MZT) is the most critical phase during embryogenesis and coincides with the transition from maternally to zygotically produced AMPs. These changes go in hand with changes in microbiome density and diversity.^{48,71} Community assembly during embryogenesis and posthatching follows specific trajectories, but it is so far not clear whether the cuticle stage microbiome serves as a microbial pool for the hatching polyp

additive and synergistic interactions of commensal bacteria are contributing to full fungal resistance. These observations highlight the importance of resident microbiota diversity as a protective factor against pathogen infections.

Observations in a number of other invertebrates and vertebrates strongly support the view that in addition to being integral components of the innate immune system, microbes should also be considered partners in animal development. Bacterial contributions are indispensable, for example, in shaping the immune system and development of organs such as the vertebrate intestine or the squid light organ [reviewed in (7)]. Animal development has traditionally been viewed as an autonomous process directed by the genome. It seems that we have to rethink development at least in part, as an orchestration of both animal-encoded ontogeny and interkingdom communication. The beneficial microbiota is a complex and multifunction ecosystem that is essential to the development, protection, and overall health of its host. Thus, the microbiota appears to function as an extra organ, to which the host has outsourced numerous crucial metabolic, nutritional, and protective functions. Studies from cnidaria to primates indicate that the host's role far outweighs other environmental factors in molding the composition of the microbiota. AMPs appear to be key factors for host-bacteria co-evolution and the driving force that leads to changes in microbiota composition. Finally, and maybe most important, the dynamic relationship between symbiotic microorganisms and environmental conditions results in the selection of the most advantageous holobiont.

4 | COMPETING FORCES ARE ALSO THE KEY COMPONENTS IN SHAPING THE BACTERIAL COMMUNITY

Microbial species rarely exist in isolation or as single-species populations but rather as dense and often diverse communities as detected by several studies in a range of habitats.^{54,55} This suggests that microbial interactions play a pivotal role in the establishment and resilience of populations in different abiotic environments. The same is thought to be true for eukaryotic organisms as they function as environments for their associated microbes and have been co-evolving with them. That is evident in host mechanisms that do not simply exclude all microbes from the environmentally exposed host surfaces but finely regulate the associated bacterial communities.⁵⁶

This can also be observed for the host *Hydra*, where the associated microbiome is not a random assemblage of bacteria from the environment, but a very specific community despite the fact that the polyps are in continuous close contact with the surrounding bacterioplankton.^{41,42,44} From the available pool, bacteria are selectively recruited, depending on not only host immunity and genetic background^{42,44} but also on the interactions between the co-occurring microbes, host physiology, and the specific environmental conditions.^{57,58} Evidence has accumulated that hosts should be viewed as "ecosystem engineers that manipulate general, system-wide properties of microbial communities to their benefit".⁵⁹

4.1 | Microbial colonization of *Hydra*

Before colonization, microbes must reach a host's surface, likely through diffusive or convective passage and active swimming.⁶⁰ In a recent article Tout et al.⁶¹ suggest that motility and chemotaxis are important bacterial traits for the establishment of specific coral-bacterial interactions. They outline the mechanism through which chemical gradients associated with coral surfaces attract particular microbial species and so lead to the specific composition of coral reef bacterial communities.

This might also be true for *Hydra*, as motility and chemotaxis are prevalent traits among the *Hydra*-associated bacteria [(62), Deines, personal communication]. Moreover, evidence is accumulating that the colonizing bacteria sense and respond to *Hydra*'s chemical landscape and actively move towards the host (Deines, personal communication). It is very likely that the colonization of *Hydra* already occurs on a very fine scale, as a specific microbial composition is associated with distinct parts of its body (Augustin, personal communication). Such a colonization of a preferred surface microenvironment is known from biofilms, where bacteria respond to very distinct environmental signals, enabling them to occupy their specific niche.⁶³

A critical step in the process of colonization is the adhesion to a surface, which can either be reversible or irreversible.⁶⁴ It is postulated that the colonization potential of a bacterium on various substrates can be described by its "secretome", which includes both the secretion systems and their protein substrates.⁶⁴ This concept offers not only a lot of potential in terms of investigating colonization factors in the context of infection but also in determining their involvement in the colonization of host species by their specific microbiota.⁶⁴ It is, however, unlikely that hosts are merely passive bystanders in the colonization process as there is selection on hosts for managing their microbiome.⁶⁵ The role of host factors in regulating microbial adhesion at epithelial surfaces has recently been addressed by McLoughlin et al.⁶⁶ Using an individual-based modeling approach, they predict that the host changes the competitive potential of particular microbes and can also create refugia for slow-growing species. The host can, for example, select for or against certain microbes through the release of specific adhesive molecules from its epithelial surfaces or through an increase in mucus flow, respectively. There is evidence from the *Hydra* system that supports the model prediction that the host selects for specific microbes. When studying the population dynamics of the two main colonizers of *Hydra* [*Curvibacter* sp. (AEP1.3) and *Duganella* sp. (C1.2)] in vitro *Duganella* sp. quickly outgrows *Curvibacter* sp. and eventually pushes it toward extinction irrespective of their initial frequencies.⁶⁷ This is in contrast to the relative abundances found on the host. Here, *Duganella* sp. is only the second most dominant colonizer with 11.1%, and not able to outcompete the main colonizer *Curvibacter* sp. that reaches 75.6%.⁵³ Such frequencies are also reached when letting both bacterial species colonize sterile *Hydra* at different initial frequencies. In contrast to the in vitro findings, on the host *Curvibacter* sp. is able to outcompete the faster growing *Duganella* sp. strain. This showcases the role of the host in controlling and shaping the abundance and diversity of its microbiome. Whether this result is due to host secretions,

host-epithelial feeding, host immunity, or a combination of all is currently being investigated.

Hydra can reproduce either asexually or sexually. Under favorable conditions *Hydra* reproduces via asexual budding.⁶⁸ When population densities are high or environmental conditions deteriorate, *Hydra* reproduces sexually through the formation of ectodermally located testis and oocytes.⁶⁹ Following fertilization, oocytes develop outside the female. Embryonic development begins with radial cleavages forming a coeloblastula about 8 h postfertilization, subsequently followed by gastrulation (Figure 2). At the end of gastrulation, about 24 hours postfertilization, cells of the outer layer develop filopodia (spike stage), and finally secrete cuticular material forming a thick multilayered protective structure ending in the cuticle stage (3 days after fertilization).⁷⁰ After a variable period of time (2–24 weeks) the small polyp hatches from the cuticle with its head first. It has been shown that each of these different developmental stages serve as a substrate for a specific set of microorganisms.^{48,71} Early embryos, for example, harbor significantly fewer bacteria than later developmental stages, such as spike and cuticle stage. This result is likely caused by an effective and specific antimicrobial defense system, which has been termed *Hydra*'s "be prepared" embryo-protection strategy.⁴⁸ This early defense is composed of maternally synthesized AMPs of the periculin family that shape the initial colonizing bacterial community. The cuticle stage in contrast is characterized by a ~30-fold

increase in bacterial load. One explanation for this could be that this is a stage where the host does not possess any control, and it thus functions as a passive settling substrate for the bacteria.⁴⁸ Alternatively the host could also actively promote growth and attachment of a very specific bacterial community by host-epithelial feeding (spike and cuticle stage are characterized by an additional outer matrix). This could form the starting community for *Hydra* hatchlings eclosing from the cuticle. At present it remains unclear whether the environment within the cuticle is germ free or whether it is also colonized by specific bacteria. These bacteria could be of major importance for the eclosing process of the hatchling or for later development and growth. Recent evidence from humans suggests that such a scenario is not unlikely. Collado and coworkers proposed that the stepwise microbial gut colonization process may be initiated already prenatally/in utero by a distinct microbiota in the placenta and amniotic fluid.⁷² Whether a prenatal bacterial microbiota exists across the tree of life is as yet unknown.

After the *Hydra* hatchling successfully eclosed from the cuticle, its epithelium is colonized by microbes from the environment and the outside (and potentially inside) of the cuticle (Figure 2). Colonizing bacteria are most likely attracted through host metabolites, ie, through the specific chemical landscape of the *Hydra* hatchlings (see above for more detail). Once microbes have reached a suitable niche, eg, a host, they must establish themselves through physical attachment to the niche or they will drift away. This can happen via bacterial capsular polysaccharides or appendages such as pili and fimbriae with which bacteria can either directly attach to the host tissue, its extracellular proteins, or other microbes with which they form biofilms.⁷³ Resources for bacterial survival and reproduction either stem from the surrounding environment, the host, or from other neighboring microbes (for possible metabolic interactions between microbes see Box 2). Essential resources for microbes comprise of micronutrients such as iron and salts and macronutrients such as complex carbohydrates as indicated by a recent study on the mice intestinal microbiome.⁷⁴

The succession of the microbial colonization of *Hydra* hatchlings was monitored for up to 15 weeks,⁷¹ and found to go through defined and reproducible stages (Figure 2). A high number and rich diversity of bacterial species characterized the initial colonization phase, which was replaced in the second week by a transient adult-like profile. Four weeks after hatching a stable adult-like pattern emerged, characterized by a low diversity microbiome that was dominated by the species that are characteristic for *Hydra*'s adult stage with the predominance of *Curvibacter* sp. With the help of a theoretical model, the cause of the observed microbial colonization pattern was predicted to likely be caused by both, host factors, such as the innate immune system, and frequency-dependent bacteria-bacteria interactions.⁷¹ The host immune response is thought to reduce the fluctuations in bacterial community dynamics, whereas the composition of a stable microbiome seems to depend upon initial colonization of one (later the most abundant) community member.⁷¹

These results are in line with more general predictions, where one or few "keystone species" are founders of the community and

Box 2 Types of interactions between species

Interactions between organisms can generally be defined with the help of the 'intra-action compass',⁸⁸ which characterizes all possible interactions among members of the same or different species. Species interactions (in microbial communities) can be driven by diverse features such as metabolism, social traits (production of public goods), or environmental factors, like spatial organization.^{89–92} There are six different kinds of basal interaction patterns present in nature, which can be used to describe the ecological interactions between members of two different (microbial) species (for potential interactions within the metaorganism *Hydra*, see Deines and Bosch²⁴). For the species involved, interactions can have a positive (+), a negative (-), or no impact (0). When the interaction for the species involved is a win-win relationship (+/+) it is known as cooperation (in metabolic terms: syntrophy). Win-loss interactions (+/-) are classical predator-prey relationships (in metabolic terms: food chain with waste product inhibition). The loss-loss relationship (-/-) describes competition between species (in metabolic terms: substrate competition). Amensalism (0/-) is an interaction in which one partner is harmed without conferring an advantage to the other (in metabolic terms: waste product inhibition). In a commensalistic relationship (0/+), one partner benefits without helping or harming the other (in metabolic terms: food chain). But also no interaction (0/0) can be found between species (in metabolic terms: no common metabolites).^{92–94} Disentangling the network of interactions between microbial species is challenging but a combination of bottom-up and top-down approaches is available, ranging from experimental (in vivo, in vitro) to in silico modeling approaches.

determine the ultimate composition and function of, eg, the human gut microbiome. This concept stems from conservation biology, but has successfully been transferred to bacterial community composition in a diverse range of ecosystems.^{75,76} It is thought that the host in turn controls his microbial community by managing the “keystone species”, rather than controlling each microbial species of its rich microbial community individually. This has been also recently shown for plant microbiomes,⁷⁷ where particular microbes, termed “hub microbes”, have been found to be disproportionately important in shaping the microbial community in the phyllosphere (eg, controlling the abundance of other bacteria). Importantly microbial “hubs” are strongly interconnected and take a central position in their microbial networks. The identification of “keystone” or “hub” species are promising targets for controlling host-associated microbial communities in health and disease, and may open up new avenues for the identification of bacteria that can specifically be targeted.

Another component that might contribute to the predominance of *Curvibacter* in *Hydra* is the virome (see below). Current evidence suggests that the virome is responsible for modulating the structure and function of host-associated communities [(78); Figure 1].

4.2 | Stability of bacterial communities in *Hydra*—The central role of competing forces

Bacterial communities are species assemblages that occupy a specific habitat where they compete for environmental resources. These complex multispecies communities can be remarkably stable and resilient, examples include microbial mats in the ocean and host-associated microbiomes such as the gut of many insects and animals and humans.^{55,58,79,80} A stable microbiome can also be observed in *Hydra*. Here, polyps in their natural environment and individuals that have been maintained under laboratory conditions for >30 years harbor a surprisingly similar microbiome that is characterized by certain core community members.⁴¹ The relevance of the concepts involved in retaining stability within microbial communities has been recently outlined by Shade et al.⁸¹ They identify interactions between different bacterial strains and species as one important factor in maintaining community stability. The response of the community to perturbation accordingly also depends on the particular interspecies interactions, and cannot be predicted based on the sum of individual-species traits alone.⁸¹

Studies have identified cooperation between microbial species as the interaction type that drives a productive and stable microbiome, eg, in the human gut.^{82,83} This view has been challenged by recent mathematical analyses⁵⁹ that predict cooperation among microorganisms to indeed increase microbiome productivity but to negatively affect microbiome stability. The counterintuitive result that cooperation between species is destabilizing is based on positive feedback loops that lead to runaway effects.⁵⁹ This means that unconstrained cooperation leads to an ever-increasing abundance of the cooperating species, which in turn can result in the collapse of competing populations and eventually in the destabilization of the whole community.⁸⁴

Until very recently models predicted that high species diversity hinders community stability.^{85,86} This is in contrast to empirical

observations where the opposite has been observed, eg, in the human microbiome.^{79,87} These models focused on species networks with a random distribution of interaction types (Box 2). Most recently, however, in ecological network models, Coyte et al.⁵⁹ introduced negative-feedback loops by increasing the number of competitive interactions in the network. This resulted in a stabilizing effect on the community. These models predict that competition between various members of the bacterial community is the main factor for maintaining a stable microbiome.

Even though models are valuable for making predictions, tractable experimental model systems are needed to be able to test these. Concerning interactions within the bacterial microbiome, testing the aspects leading to stability is of great importance, as also pointed out by Fischbach and Segre.⁵⁶ We are certain that the *Hydra* model will make a useful contribution in understanding host-associated microbial communities, as we are currently collecting data on the strength and nature of the ecological interactions between its different microbial species (Figure 1).

Another factor facilitating the stability of its microbiome is the host itself.⁵⁹ Several mechanisms have been identified by which a host may be able to suppress the positive feedback between cooperating species and weaken their interaction. In the following we summarize the available evidence from *Hydra* where the host shapes the interactions between microbial species: (i) regulation through the immune response is dependent on the density of a particular microbial species. Observations in the *Hydra* system where an increase in abundance of certain members of the microbiome, ie, Oxalobacteraceae and *Pelomonas* sp., provoke a targeted immune response^{48,95} is indicative of such a mechanism. Specifically have the host's AMPs hydramacin and arminin been observed to increase in their expression levels after the increase in abundance of the two microbial species. This could potentially have a negative effect on the positive feedback loop between these two microbial cooperating species, as AMPs are known to selectively target specific taxa, while not affecting others.⁹⁶ Nevertheless, the observation still needs to be experimentally tested to confirm causality. (ii) spatial segregation reduces between-species contact and so minimizes interactions. After microbes adhere to surfaces they start to grow, divide, and interact with each other forming matrix-embedded communities, termed biofilms. The structure of these communities can be either a disordered mixture of strains or it can become highly structured such that the final community contains large patches of single species.⁹⁷ The same principles can be assumed to apply for *Hydra*'s ectodermal glycocalyx surface, a habitat for a complex microbial community. Very recent findings provide the first evidence that *Hydra*'s microbiome is spatially structured. Augustin et al. (personal communication) show that a specific host neuropeptide in *Hydra* leads to a spatial distribution along the body axis of the main colonizer *Curvibacter* sp. (Figure 1). (iii) Provisioning of carbon sources via epithelial feeding minimizes cross-feeding between microbes. For humans it is well established that the gastrointestinal mucus layer not only limits the contact between microbes and epithelial cells but also serves as a food source for many gut bacteria.⁹⁸ The types of modifications of mucins and the downstream effects on community members

are complex but it has been hypothesized that carbohydrates play an important role in the interaction between host and microbes.⁹⁹ There is also evidence from corals that the mucus is used by commensal bacteria,¹⁰⁰ which strongly suggests that such metabolic interactions are also present between *Hydra's* glycocalyx and its microbiota—an aspect that is currently under investigation.

5 | WHICH ROLE DO VIRUSES PLAY IN THE COMPETING INTERACTIONS?

The freshwater polyp *Hydra* is not only associated with bacteria they feature a diverse eukaryotic viral community and bacteriophages. Eukaryotic viral community identified in *Hydra* affiliate to, eg, Phycodnaviridae, Herpesviridae, Baculoviridae, and Poxoviridae.¹⁰¹ Viruses of these families are known to cause severe disease in a variety of different organisms including plants, vertebrates, and invertebrates. Most of the recognized viral infections are acute viral infections with a rapid progression of disease, a restricted period of disease symptoms followed by a final clearance of the viral infection by the host immune system. The host innate immune system is a fast defense mechanisms responding within the first minutes after viral infection. Pathogen-associated molecular patterns (PAMPs) such as viral proteins, glycoproteins, RNA, or unmethylated CpG in viral DNA are recognized by pattern recognition receptors (PRR), eg, RIG-1, NOD-like receptors, or TLPs leading to RNA synthesis of cytokines, eg, interferon α , and β TNF- α , IL-6, IL-12, and IFN- γ .¹⁰² Cytokines stimulate the production of AMPs. Antimicrobial peptides are important effectors of innate immune system regulating bacteria, fungi, but also viruses. Antimicrobial peptides such as defensins can either act directly on viruses or indirectly by affecting target cells.¹⁰³ However, not all viral infections are entirely cleared. Some viruses evade the host immune defense and establish persistent infections (eg, humans varicella-zoster virus, measles, HIV, cytomegalovirus). These infections can be chronic with a continuous proliferation of virions for a long period or viruses switch from a lytic to a latent state where their nucleic acid is integrated into the host genome. Virome sequencing and increase in genomic data revealed that persistent viral infections are common and present in all domains of life. Also *Hydra* is associated with a species-specific persistent viral community that can be expected to modulate *Hydra's* functions.

5.1 | Host-virus interaction

In the same way host has evolved to control viral infections, viruses have developed a variety of different mechanisms to manipulate their host. For this reason host-virus interactions have a profound impact on cellular pathways and influence the host metabolism. Several viruses are known to stimulate host interleukin pathway (human immunodeficiency virus HIV, hepatitis C hepatitis B) or produce their own viral orthologue (herpesviruses and poxviruses). Interleukins are crucial for many viruses to establish persistent infections and blockage of this pathway facilitates virus clearance. Consequently,

different aspect of the chemokine system had been exploited by viruses and viruses encode proteins with homology to chemokines and chemokine receptors.¹⁰⁴ Host-viral interactions are not only present during acute infections. Most of the viruses remain active throughout latency. Epstein-Barr virus latency persists in B cells, epithelial cells, and T cells. It remains active and expresses genes manipulating cellular gene transcription, induces G1 arrest, chemokines, promotes cell proliferation, activates NF- κ B, p38, and other pathways, blocks antigen-dependent signaling, suppress differentiation, promotes epithelial cell spreading, and inhibit apoptosis.¹⁰⁵ *Baculoviruses* that were also found in the virome of *Hydra* and replicate within *Hydra* tissue (Figure 3) are another well-studied example of how viruses manipulate their hosts. Already during *Baculovirus* latency a subset of genes are transcribed and interact with cellular pathways. A variety of immediate early, early, and late gene products manipulates cell-cycle arrest, remodel cytoskeleton, metabolism, immune response, and inhibit apoptosis.¹⁰⁶ Similar interactions between host and viruses have been reported for herpesviruses. Herpesviruses are already associated with basal metazoans *Hydra* and corals.^{100,107} Along the phylogenetic tree herpesviruses are present in a variety of animals, ranging from molluscs,¹⁰⁸ fish,^{109–111} birds,¹¹² to humans, among others. This ancient association between herpesviruses and metazoans has coevolved a strong interaction of herpesviruses and their hosts.¹¹³ In *Hydra* and corals herpesviruses are one of the most abundant viruses representing more than 50% of the associated eukaryotic viral community^{100,107} and there is first evidence that they play a beneficial role in sustaining coral health.¹¹⁴

Viral-induced reconstruction of cellular functions may affect only a small subset of cells and remain locally controlled with little impact on the entire individual. Severity of viral infections and the switch from latent to lytic viral replication highly depends on the type of virus and environmental factors that influence virus-cell interactions.¹¹⁵ Oncogenic viruses are one example that virus-induced cell manipulations can have severe consequences for its host.¹¹⁶ However, not all viruses are negative and it can be expected that most of the viruses are neutrally associated with their host or even have a positive impact. In *Hydra* we identified a diverse viral population, which has not been recognized so far as *Hydra* is presumed to be immortal under constant laboratory conditions and does not show any signs of disease symptoms. However, under temperature stress condition we can induce some shifts in the natural viral community composition leading to, eg, an increase in *Baculoviruses*. Persistent viral infections that are sensitive to environmental stress might function as selective regulators within the diverse cell population. In latent virus-infected cells that are not able to compensate for environmental imposed alterations of viral-cell interaction the viral lytic lifecycle is induced finally terminated by the death of the cell. Thus, viruses are selective and able to function as regulators within cell populations with a positive impact on its host as illustrated by oncolytic viruses.^{117,118} Several viruses are able to infect cancer cells and replicate within these cells. Although oncolytic viruses can infect normal cells, cancer cells are due to several different defects regarding cellular signaling and stress response, favorable for viral replication.^{117,118}

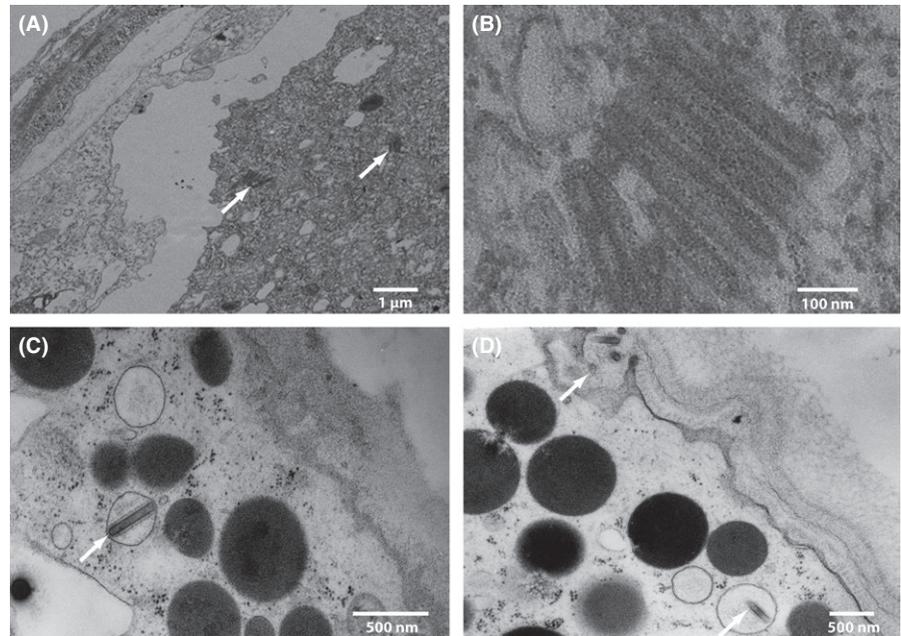

FIGURE 3 Baculoviral replication in *Hydra*. Transmission electron micrographs of ultrathin sections of *Hydra* negatively stained with uranyl acetate illustrating the presence of *Baculoviruses* in *Hydra* tissue. *Baculoviruses* are replicated within *Hydra* cells (A and B). Virions are transported in vesicles (C) and released through the ectodermal cells (D)

5.2 | Virus-virus interaction

Viral infections do not only affect the host but they also impose a strong impact on other viruses. Virus-virus interaction can be directly mediated through viral genes and gene products or indirectly through viral-induced alteration of the host (detailed reviewed in DaPalma et al.).¹¹⁹ Being associated with a diverse viral community like *Hydra* implies complex virus-virus interaction already within the host-associated viral community. Secondary invading viruses from the surrounding water encounter the present viral community that have already coevolved with its host and established a homeostatic relation or balanced association with their host cells. This viral-related reprogramming of host cells shape the present cell population and can induce resistance to subsequent infection by similar viruses (superinfection exclusion).¹²⁰ Environmental stress can destabilize natural host-viral homeostasis, which may facilitate secondary invasion by tissue damage and loss of barrier functions.^{101,107} There are also several examples in the literature of cooperative virus-virus interactions. In these cases viral infection depends on viruses that have previously infected and modified the host cell in the way that a secondary virus is able to infect (eg, human retrovirus).¹²¹ On the other hand secondary viral infection can also transactivate latent viruses of the host. Transactivation of latent viruses can be triggered directly by gene products of another heterologous virus or indirectly by changing the expression of host genes. Most of these interactions within the viral community occur on a cellular level and only affect a subset of the cell population without causing any visible disease symptoms. Double infections are then recognized, eg, if they cause an acceleration of disease. For this reason most of these interactions remain unseen. However, increasing number of reports illustrating the complexity of viral communities associated with metazoans points to complex viral-viral interactions within metaorganisms. Multiplicity of viral infections of one individual implicates an increased chance that co-infections

appear within one cell. This may lead to a diversification of viruses by genetic recombination of parental viruses, generation of pseudotyped viruses, or to the integration of, eg, retroviruses into the genome of other viruses.

5.3 | Virus-bacterial interaction

Viral infections often lead to the debilitation of the host facilitating secondary infections by bacteria. This can be due to disturbance of barrier functions, such as virus-induced cell death or change in host cell membranes leading to an increase in bacterial attachment. Viral alteration of the immune system reduced expression of AMPs or downregulation of TNF- α .^{122,123} While these inside-out regulations implies an already established virus-host association, novel invading viruses have to cross not only natural barriers, such as mucus layers, but also glycocalyx and cell membranes of the host (Figure 1). In most organisms and also in *Hydra* these surfaces are already colonized by commensal microbiota. Host-bacterial but also bacteria-bacteria interactions shape the surface environment, which can highly impact the infectivity of eukaryotic viruses.¹²⁴ While there are several examples of probiotic bacteria featuring antiviral activity, it becomes more and more apparent that these effects are most likely mediated indirectly by bacteria-induced modulation of the host immune response.¹²⁵ In general, the presence of commensal microbes leads to an upregulation of immune responses suggesting germ-free individuals to be more susceptible for viral infections due to a compromised immune system. However, this causal link is only true for some viruses. As viruses have coevolved with its host and its associated microbes, infectivity of several viruses highly depends on the presence of the associated microbial community. For example, transmission of retrovirus depends on the commensal microbiota to induce an immune evasion pathway.¹²⁶ Poliovirus infection depends on lipopolysaccharides (LPS) produced by its host-associated bacteria protecting the virion from inactivation

and enhances viral attachment to cellular receptor.¹²⁷ This and several additional examples of virus-bacteria interactions are reviewed by Robinson and Pfeiffer.¹²⁸

5.4 | Phage-bacterial interaction

In the aquatic environment *Hydra* is permanently exposed to bacterial colonizers as well as to phage infections that interfere with the host-specific microbiota. Preventing foreign bacteria from settlement and control phage infection are beside the internal regulation of the host-associated bacterial community important for the maintenance of host-specific bacterial community composition. Phages are compared to bacteria highly abundant^{129,130} and strong regulators within bacterial populations.¹³¹⁻¹³³ Maintaining a stable microbiota implies strong defense mechanisms against phage infections. As phages evolve rapidly bacteria have developed a broad range of strategies to protect themselves from infection. Mechanisms to control phage infections have been reviewed in detail^{134,135} and can be grouped into (i) preventing phage attachment by blocking phage receptors, excretion of extracellular substances, or production of competitive inhibitors; (ii) blocking DNA entry; (iii) cutting phage nucleic acid by restriction modification or Crisper-Cas system; (iv) abortive infection; (v) assembly interference; (vi) blocking phage DNA replication by BREX system;¹³⁶ and (vii) arbitrium communication system.¹³⁷

Living associated with *Hydra*, embedded into the mucus-like layer of *Hydra's* glycocalyx⁴⁵ could be another so far neglected mode of protection of bacteria against phage infections. An accumulation of virus-like particles (VLPs) at the surface of mucus layers have been reported for different organisms and it has been shown that phages bind to mucus glycoproteins via Ig-like proteins domains on phage capsids.¹³⁸ While this observation can be interpreted on one hand as host-derived protection of its associated bacteria against phage infection, the authors hypothesize that the presence of phages at the outer mucus layer could serve as a non-host-derived immune defense. While the function of phages within host-derived mucus layers is still in its infancies more research has been conducted on bacterial biofilms. Similar to bacterial communities that live within host-derived mucus layer, biofilm bacteria live in a three-dimensional matrix of exopolysaccharides (EPS). Living within a biofilm not only protects bacteria from physicochemical stress, it also protects bacteria from phage infections. Some phages have adapted to this environment and carry polysaccharase to actively degrade EPS-enabling attachment to bacterial surfaces for infection.¹³⁹ Analogous to biofilms phage invasion of the mucus-like layer of *Hydra* can be expected to afford evolutionary adaptation to overcome this natural barrier. Nevertheless, bacteria living in the periphery are more likely to get infected than those deeper inside.

Recently, we have analyzed the phage community composition of different *Hydra* species and revealed that *Hydra* is associated with a species-specific phage community.¹⁰⁰ It can be expected that the phage population is composed of transient phages by meaning phages that originate from the surrounding water and adhere to *Hydra's* surface or infect *Hydra's* associated microbiota and of a resident phage community. First insides into the resident phage population we gained

by simple bacteria-bacteria interaction experiments between the most dominant bacterial colonizer of *Hydra* *Curvibacter* sp. and the second abundant bacteria *Duganella* sp. in vitro.⁶⁷ The observed frequency-dependent growth rate was not explainable by only two interacting bacterial strains and a phage as third player was predicted. Screening the genome of both bacteria revealed the presence of a prophage signature in the genome of *Curvibacter* sp. Finally, we were able to reactivate the temperate phage of *Curvibacter* sp. and could show that this phage is able to cross-infect *Duganella* sp. The presence of hidden prophages within *Hydra*-associated bacteria directed us to screen our bacterial culture collection for the presence of lysogenic phages and we found that approximately 50% of *Hydra*-associated bacteria carry a prophage in their genomes. In this lysogenic state of bacteriophage lifecycle phage DNA is integrated into the bacterial genome and is replicated passively during bacterial cell division. Analogue to latent eukaryotic viral infections lysogenic phages are transcriptional active and able to modulate their bacterial host, eg, metabolism, virulence factors, and stress tolerance.¹⁴⁰ This lysogenic conversion increase the genetic repertoire of the bacterium by horizontal gene transfer but may also change or shape host-bacterial interactions, eg, by modifying outer-membrane LPS.¹⁴¹ Carrying a prophage can be beneficial as it protects the bacterium from similar phage infections by superinfection exclusion. Switching from a lysogenic to a lytic lifecycle can be advantages for the bacterium as their phages can serve as weapon against competitors. This in turn can have regulatory functions within the *Hydra's* associated bacterial community and prevent bacterial invasion from the surrounding environment. Prophages of *Hydra*-associated bacteria can be reactivated and switch to a lytic replication. This switch is driven by different environmental factors but also depends on the state of bacteria growth rate, which emphasis a potential link between nutrition and both function and stability of the associated microbiota. Thus, prophages can be induced under environmental stress conditions it can be expected that *Hydra*-bacteria-phage interactions are dynamic systems, which have to be continuously balanced and brought into equilibrium to finally maintain metaorganism homeostasis. Moreover, it can be speculated that host factors, such as AMPs, can also interfere with the lysogenic state of bacteria and are able to induce phage replication.¹⁴² Host intervention in bacterial-phage interaction might be one potential mode to fine-tune bacterial-phage interactions and to control its specific microbes by using prophages as internal regulators. On the other hand proliferation of phages by the host-specific bacterial community could help to defend against secondary bacterial infection according to the bacteriophage-mediated immunity proposed by Barr et al.^{138,143}

6 | CONCLUSION

How a metaorganism is established during ontogeny and remains in balance over time is a critical question regarding many aspects of life. Here, we propose that *Hydra* is an informative model system to explore how the microbiome and virome are established and maintained under different environmental conditions. Ontogeny is a process in which

the associated partners bacteria, phages, and viruses are exposed to a consecutive pattern of a newly shaped host environment. Varying environmental conditions during development can reshuffle complex interactions within the holobiont assemblage, which form and prime the metaorganism. We propose that not only the holobiont composition, but even more the network of interactions that have been established within the holobiont during ontogeny contribute to the stability of the metaorganism. Development of a metaorganism continues throughout the lifespan of the host allowing a continuous fine tuning of the established network under varying environmental conditions ensuring the function and homeostasis of the metaorganism.

ACKNOWLEDGEMENTS

The authors apologize that because of the selective focus, many interesting investigations and reviews were not included. The authors' work related to this topic was supported in part by grants from the Deutsche Forschungsgemeinschaft (DFG), the Collaborative Research Center (CRC) 1182 ("Origin and Function of Metaorganisms"), and grants from the DFG Cluster of Excellence programme "Inflammation at Interfaces". PD acknowledges funding from the European Union's Framework Programme for Research and Innovation Horizon 2020 (2014-2020) under the Marie Skłodowska-Curie Grant Agreement No. 655914 and from the Deutscher Akademischer Austausch Dienst (DAAD). TL acknowledges funding from the Volkswagen Foundation (Funding program "Experiment!—In search of bold research ideas"). TB gratefully appreciates support from the Canadian Institute for Advanced Research (CIFAR).

CONFLICT OF INTEREST

The authors declare no conflicts of interest.
